Abstract

Artificial neural network models have been already used on many different fields successfully. However, many researches show that ANN models provide better optimum results than other competitive models in most of the researches. But does it provide optimum solutions in case ANN is proposed as hybrid model? The answer of this question is given in this research by using these models on modeling a forecast for GDP growth of Japan. Multiple regression models utilized as competitive models versus hybrid ANN (ANN + multiple regression models). Results have shown that hybrid model gives better responds than multiple regression models. However, variables, which were significantly affecting GDP growth, were determined and some of the variables, which were assumed to be affecting GDP growth of Japan, were eliminated statistically.

Keywords: Artificial neural network; Hybrid model; GDP growth of Japan; Modeling forecast; Variable determination

Introduction

For the past several decades ANN has been successfully used in a wide range of study of fields [1,2]. The recent upsurge in research activities into artificial neural networks (ANNs) has proven that neural networks have powerful pattern classification and prediction capabilities. Yet, neural networks are rather young in forecasting macroeconomic variables and becoming a more attractive tool alongside traditional econometric models. Kuan and White have theoretically defined practicability of neural networks in forecasting econometric models. Swanson and White [3] following Maasoumi, Khotanzad, and Abaye have applied artificial neural networks to model nine different macroeconomic variables. This paper compares the relative usefulness of different linear and nonlinear models using a wide array of out-of-sample forecasting performance indicators. Their major conclusion is that multivariate linear models are marginally better overall.

Kohzadi et al. compared ANN and ARIMA models to forecast the future of cereal and demonstrated that the forecast error of neural network model is between 18 to 40 per cent lower than that of ARIMA. DÜZGÜN R. forecasted GDP Growth of Turkey and compared the results of ANN and ARIMA models and found that ARIMA model performed better than neural network model. Moshiri and Cameron used Back Propagation Artificial Neural Network (BPN) models in comparison with econometric models to forecast inflation rate. The performance of hybrid BPN was as well as traditional econometric models and even better in some cases.

Krugman [4] states that one of the several outbreaks during the 1980s was Japan’s bubbles which were mainly financed by bank loans. Kaihatsu [5] supports Krugman [4], arguing that “Great Stagnation” of Japan in 1990s was due to the dysfunction of the financial system stemming from the collapse of asset price bubbles in the early 1990s. Hayashi and Prescott [6] believe that the reduction of workweek length in the 1988-1993 periods has an important impact on the economic stagnation which brought the revision of Labor Standard’s Law. Cargill and Parker [7] summarize the causes of Japan’s downturn in a seven-step sequence which is attributed to tight monetary policy applied by Bank of Japan. The author holds Bank of Japan some responsibility for the stagnation.

After the recovery of Japan’s economy in 2003 it has experienced a severe economic contraction in the fourth quarter of 2008. Exports fell by 12.5 per cent in 2008 followed by 36.8 per cent fall in in the first quarter of 2009 [8]. In addition, one of the remarkable features of 2008 crisis is the collapse of international trade [9].

In this research, it was observed that GDP growth of Japan was decreased dramatically (-5.527) in 2009. Based on the information above, it can be concluded that this decrease is because of global crisis that started in 2008. On the other hand, data indicates that GDP growth in 2010 was 4.652. These two impulses seem to be abnormal and makes forecast error increase. Furthermore information about data will be given the section 3.1.

Methodology

Data

Secondary data was taken from the original site of World Bank. Data includes the GDP growth of Japan from 1974 until 2013. There is plot of data below (Figure 1).

It can be observed from the graph that GDP growth data had a normal fluctuation until 2008 global economic crisis but after economic crisis, in 2009, GDP growth dramatically decreased. This decrease was an abnormal impulse and models had difficulty to catch this impulse. On the other hand, in 2010 Japanese GDP growth has jumped up and in these two consequent years a gap has occurred and this gap has increased the error level of forecast models. Out of these abnormal impulses, both multiple regression models and hybrid ANN models succeeded catching the points. Finally, models were compared despite of those abnormal fluctuations and results were discussed at the conclusion section.

Models used for forecasting

This part introduces the models that were used in the research. Models are multiple regression models and artificial neural network models. Artificial neural network model is used hybrid with the support of multiple regression models.

Multiple regression models: Multiple regression models were widely utilized in economical researches [10-12]. Multiple regression analysis helps a researcher to determine the effects of each independent variable on dependent variable [13]. If there is an output like production, GDP growth…etc., there must be some variables which affect the level or quality of that output. In this case the GDP growth of Japan is taken as output. In this case the factors that affect the GDP growth will be tried to be determined. Effect of each factor or variable might be shown as;

\[ Y = \beta_0 + \beta_1 w_1 + \beta_2 w_2 + \beta_3 w_3 + \beta_4 w_4 + \beta_5 w_5 + \beta_6 w_6 + \ldots + \beta_n w_n \] (1)

Here the meanings of the variables are:

- \( Y \): Is the dependent variable that is searched for in the next period.
- \( \beta_0 \): Is the constant of regression line.
- \( \beta_i \) (1-n): Is the coefficient of the concerning parameter on dependent variable. It doesn’t have to be the same for each independent variable. It depends on how much this independent variable effect the dependent variable.
- \( W \) (1-n): Is the unit of each independent variable (Interest Rate, Inflation, M1…etc.) that effect the dependent variable (GDP Growth).

In this research the dependent variable is taken as GDP Growth and independent variables are initially determined as 12 variables such as year, long term interest rate, short term interest rate, interest rate yield spread, consumer price index, inflation expectation, real short term rate, M1, real M1, M2, real M2, and real GDP. Initially, coefficients of all variables those researchers think has an impact on GDP Growth were analyzed by IBM SPSS 20. The performance of the ENTER module of the software is shown as; The Table 1 above shows that totally dependent variables explain 83.6% of the total factors. This is a normal level for the acceptance. Durbin-Watson test result is 2.56. It shows that there is no autocorrelation within the factors. Normally the acceptable level of this test should be between 1.5-2.5 but this result is a bit above than the upper control limit. F test of the regression model is shown below (Table 2).

Results of ANOVA test (Table 2) show that the model is significant because the P<=0.05 (0.000). but still we should consider t test results of the analysis because F test show overall model significance but each variables’ significance also should be determined. If there is non-significant variable, it should be excluded from the equation. The t test results of the model are;

The Table 3 above shows the coefficients of the regression equation. T test results show the significance level of each variable. It is blatant
Artificial neural network models are capable to find adequate solutions for many different kinds of problems. These models can be used for forecasting, classifying, setting...etc. Artificial neural network models are capable to find adequate solutions for many different kinds of problems. These models can be used for forecasting, classifying, setting...etc.

Number of hidden layers: This layer is called as black box of neural network models. In the literature it has been found that one or two hidden layer number is the most common ones. Otherwise it has been seen that the models were memorizing instead of learning. However, it takes more time to calculate in case more hidden layers were chosen. For these reasons we have chosen only one hidden layer.

Number of neurons: There is no specific calculation about finding the best number of neurons. Using trial and error method, we have specified four neurons finally.

Output layer: This layer is the objective layer of the problem. In our case, we have one output layer and called as GDP Growth. Totally two scenarios were used to find the best neural network model. As first scenario, 7 independent variables (Year, Interest Rate Yield Spread, Consumer Price Index, M2, Real M2, Real GDP, and result of Backward Multiple Regression Model) were used. Table 6 shows the information about the model and:

Here there are the calculations of each hidden layer and finally the neural network model is stated below;

\[ H (1.1) = 1.354 + (-0.041) \text{Year} + (0.632) \text{I.R.Y.S.} + (0.805) \text{C.P.I.} + 0.630 \text{M2} + 0.035 \text{RealM2} + 0.418 \text{Real GDP} + (-0.507) \text{BACKWARD R.A.} \]

\[ H (1.2) = 1.989 + (-1.322) \text{Year} + (0.175) \text{I.R.Y.S.} + (0.347) \text{C.P.I.} + (-0.244) \text{M2} + 0.368 \text{RealM2} + 1.094 \text{Real GDP} + (1.331) \text{BACKWARD R.A.} \]

\[ H (1.3) = 0.853 + (-0.998) \text{Year} + (0.935) \text{I.R.Y.S.} + (0.046) \text{C.P.I.} + 0.156 \text{M2} + 0.095 \text{RealM2} + 0.364 \text{Real GDP} + (-0.749) \text{BACKWARD R.A.} \]

\[ H (1.4) = -0.088 + (0.430) \text{Year} + (0.343) \text{I.R.Y.S.} + (-0.122) \text{C.P.I.} + 0.124 \text{M2} + 0.240 \text{RealM2} + (-0.086) \text{Real GDP} + (0.097) \text{BACKWARD R.A.} \]

Neural network model:

\[ Y = I (-0.738 + (-0.752) h1 + 1.542 h2 + (-0.416) h3 + 0.327 h4) \]

Here 1 (.) can be thought as an activation function in order to convert the rescaled data into the original series.

As a result, mean absolute error (MAE) was calculated as 0.732. On the other hand, mean squared error level was 0.959. The comparison will be done at the conclusion part.

Findings and Conclusion

As a result, it was observed that the filtered multiple regression analysis model performs better than the simple multiple regression model. On the other hand, hybrid artificial neural network model performs better than both filtered multiple regression model or simple multiple regression model. Here below there is a graph that shows the performances and table show about the error levels of each model (Figure 2).

It is blatant from the error levels that the hybrid ANN model gives better results than other models. From this point, GDP Growth of Japan can be calculated using “Hybrid ANN” rather than multiple regression models. This doesn’t mean that Hybrid ANN model performs the best.
In order to say this, all forecasting models must be compared with this model. But in this case it was proven that the Hybrid model performed better. Furthermore, despite of 12 independent variables used for the modeling, it was observed that not all of them significantly affected the model. That is why; non-significant independent variables have been subtracted from the model (Table 7).

As a result, it was seen that Year, Interest Rate Yield Spread, Consumer Price Index, M2, Real M2, and Real GDP variables are significantly affected the GDP Growth of Japan. On the other hand, Short Term Interest Rate, Inflation Expectation, M1, Real Short Term Rate, Long Term Interest Rate and Real M1 variables didn’t affect the GDP Growth significantly and subtracted from the model. By this way we have determined some of the factors that affect GDP Growth of Japan and proven that the Hybrid ANN model performed better than multiple regression models.
