Abstract

Super 304H austenitic stainless steel tubes containing 2.3 to 3 (%wt) of Cu is mainly used in superheaters and reheater of ultra-supercritical boilers. Welding high alloyed steels such as stainless steels can result in local variation in the weld pool during welding. The effect of current pulsing on microstructure and hot tensile properties of filler added gas tungsten arc welding (GTAW) of super 304H is studied. Current pulsing is found to be beneficial in improving the hot tensile properties of super 304H GTAW joints at all test temperature, which is attributed to the grain refinement, increase in frequency of high angle grain boundaries, reduced segregation and finer carbonitrides precipitation.

Keywords: Super 304H; Gas tungsten arc welding; Pulsed current; Hot tensile properties; Microstructure

Introduction

The need to increase the efficiency of the power plants and thereby to achieve, reduction in Co2 emissions can be attained by increasing the parameters of steam cycles. The main challenge in building power plants with advanced steam cycles is the availability of construction materials. Newer alloys are being developed and identified for the requirement of such power plants with advanced steam cycles. In such effort, super 304H stainless steel is proposed for use in super heater and reheater tubings of ultra-supercritical boilers [1]. Super 304H is capable of operating in steam temperatures of about 600°C, with excellent resistance corrosion and creep. Super 304H with addition of 2.3 to 3 (% wt) of Cu results in increased creep strength of the alloy, offered by the fine, stable, coherent Cu-rich precipitates evolve during exposure to creep conditions [1-3].

In terms of weldability, Cu may slightly increases the hot cracking sensitivity and with regard to weld metal the effect of Cu needs to be investigated [4]. Austenitic stainless steels welded by constant current gas tungsten arc welding (CC-GTAW) produce coarse columnar grains in the fusion zone of welds and such microstructure’s can result in inferior mechanical properties than the parent metal [5]. Welding high alloyed steels, such as stainless steels result in inhomogeneous weld metal with local compositional variations within the microstructure, and which can attributed to segregation of alloying elements during weld metal solidification. Segregation may result in weld joint with inferior room and high temperature properties than the parent metal.

It is preferable to control the solidification structure of the fusion zone in weld by altering the prevailing thermal gradients in the weld pool during welding [6]. In pulsed current gas tungsten arc welding (PC-GTAW) process the welding current is pulsed between high and low value for different time intervals at a pulsing frequency. The high current pulse will bring the weld zone above the melting point while the low current period in the pulse allows the weld pool to partially solidify and maintain a consistent arc. The weld bead is observed as a series of over lapped spot weld in which the overlap depends on the pulsing frequency [5,7].

Sen et al. [8] reported that Cu addition to 304H stainless steel does not embrittle the alloy during exposure to high temperature. Ha and Jung [9] reported the suitability of the steel for ultra-supercritical application. Works carried out by Yang et al. [10], Li et al. [11], Bai et al. [12] on super 304H boiler grade austenitic stainless steel revealed its good microstructural stability during high temperature exposure. However, the work on PC-GTAW of super 304H in open literature is very scant. Hence in this investigation it is planned to study the effect of current pulsing on microstructure and hot tensile properties of filler added GTAW joints of super 304H austenitic stainless steel.

Experimental Details

Super 304H austenitic stainless steel tubes of outer diameter 57.1 mm and wall thickness of 3.5 mm was used in this investigation. The chemical composition of the tubes in as-received condition and filler metal are given in Table 1. Joints with single V butt edge preparation were welded with filler addition using CC-GTAW and PC-GTAW processes. Argon was used as shielding and purging gas with flow rate of 12 and 10 liters per minute respectively, to prevent oxidation of the welds. The welding parameters used to fabricate the joints are shown in Table 2.

The photograph of the joints welded by CC-GTAW and PC-GTAW is shown in Figure 1a. Joints are inspected for defects and tensile specimens were extracted using wire-cut electric discharge machining, as per the dimensions shown in Figure 1b. Tensile tests were carried out using universal testing machine (UTM) under the constant crosshead speed mode for a nominal strain rate of 1×10^-3 S^-1 at...
**Results**

**Microstructure**

Macrographs of the CC-GTAW and PC-GTAW joints are shown in Figures 2a and 2b respectively, macrographs reveal the complete fusion of the tube joint with no macro defects. Figures 2c and 2d show the weld metal microstructure of CC-GTAW and PC-GTAW joints, consists of equiaxed austenitic grains. Figures 2e and 2f show the weld fusion line, consists of columnar austenitic grains preferentially oriented towards the weld centre, evidencing the epitaxial grain growth occurred in those regions. The heat affected zone (HAZ) of both CC-GTAW and PC-GTAW joints consist of coarser grains than the parent metal.

SEM micrograph of weld metal of CC-GTAW and PC-GTAW joints is shown in Figures 3a and 3b respectively, weld metals invariably consist of fully austenitic grains with no delta ferrite and the migrated grain boundaries in the weld metal is indicated by arrow in Figure 3b. SEM images of fusion line of CC-GTAW and PC-GTAW joints are shown in Figures 3c and 3d, which reveals the absence of delta ferrite near fusion line. EDS elemental mapping of weld metals shown in Figures 4a-4f, reveals that the precipitates in weld metal are Mo and Nb rich carbonitrides which were intentionally added in the filler wire to stabilize the higher carbon content. EDS line scan of the weld metal grain boundary shown in Figures 4g and 4h reveals no segregation of Cr and Ni to the grain boundaries. The ferrite measurement using ferrite scope revealed no indication of delta ferrite in the welds of both CC-GTAW and PC-GTAW joints.

The XRD pattern of weld metals of CC-GTAW and PC-GTAW joints is shown in Figures 5a and 5b respectively, which indicates the presence of austenite phase and no indication of delta ferrite in the welds.

**EBSD analysis**

The EBSD pole figures of cross section of CC-GTAW and PC-GTAW joints are shown in Figures 6a and 6b respectively. From the pole figures, it can be inferred that, the dendrites in the weld metal do not exist as a single entity, but it is actually part of a larger grain, where the weld metal consists of coarse grains than the parent metal [13]. The interface in the pole figure reveals epitaxial grain growth, planar solidification and grain growth in the HAZ. The grain size distribution in the weld metal of CC-GTAW and PC-GTAW joints are shown in Figures 6c and 6d respectively. From the distribution chart, it can be inferred that the number of finer grains (< 70 µm) in the weld metal is higher in the PC-GTAW than the CC-GTAW, which attributes the grain refinement achieved in the weld metal due to current pulsing. The relative frequency of misorientation between the grains in the welds of CC-GTAW and PC-GTAW joints are shown in Figures 6e and 6f. The presence of grains boundaries with lower degree of misorientation (<15°) are referred as low angle grain boundaries and are found to be less frequent in case of PC-GTAW joint than the CC-GTAW joint.

**Tensile properties**

The transverse tensile properties of CC-GTAW and PC-GTAW joints of super 304H at various test temperatures are presented in Table 3. PC-GTAW joint exhibited marginal increase in tensile strength and
percentage of elongation than the CC-GTAW joints at all the test temperatures. The tensile strength and elongation of both the joints decreased with increase in test temperature. The failure was located in the parent metal in both CC-GTAW and PC-GTAW joints at all test temperatures.

**Micro hardness**

The micro hardness profiles measured across the weld center line of CC-GTAW and PC-GTAW joints in the mid thickness are presented in Figure 7. The highest hardness value was recorded in the weld metal of both joint however, PC-GTAW weld metal exhibited lower hardness than the CC-GTAW joint. Large variations in hardness values within the weld metal region were observed for CC-GTAW joint than the PC-GTAW joint, owing to their inhomogeneous microstructure. Lowest hardness across the joints was recorded in the weld metal close to the fusion line, probably the unmixed zone (UMZ). The HAZ region of
both CC-GTAW and PC-GTAW joint has not undergone softening due to welding and retained its hardness equivalent to that of the parent metal (175 HV).

Fracture surfaces

SEM fractographs of tensile specimens are shown in Figure 8. In all the cases, fracture occurred in parent metal and the features observed are similar in CC-GTAW and PC-GTAW joints. Fracture surface of CC-GTAW and PC-GTAW joint tested at RT are shown in Figures 8a and 8b respectively. The fracture was ductile for both joints tested at RT, with fine dimples around the voids, which are associated with the precipitates, acted as crack initiation sites. Figures 8c and 8d show the fracture surface of CC-GTAW and PC-GTAW joints tested at 550°C reveals more featureless region with elongated voids and dimples. The joints tested at 550°C failed in less ductile manner than the joints tested at RT, and it is also evident from the tensile elongation (Table 3).

Discussion

PC-GTAW joint exhibited higher tensile strength and elongation values than CC-GTAW at all test temperatures with the failure at the parent metal. The mode of solidification and amount of delta ferrite in stainless steel welds can be predicted using WRC-1992 constitution diagram. The Cr and Ni equivalents of filler metal were calculated as 19.4 and 23.1 respectively and the weld metal was predicted to solidify in A-Mode with fully austenitic weld metal. The microstructural analysis of CC-GTAW and PC-GTAW joints revealed fully austenitic weld metal, with no delta ferrite as predicted. The addition of carbide forming Mo and increased addition of Nb to the filler metal had resulted in formation of Mo and Nb rich carbonitrides (Figures 4a-4f). Hence the risk of forming other detrimental carbides in the weld metal of super 304H with high carbon content was reduced. Periodic pulsing of welding current in PC-GTAW, impose thermal variation in the weld pool to enhance the flow of molten metal in the weld pool and help to reduce the compositional variation within the weld metal [5-7]. Current pulsing resulted in grain refinement (Figures 6c and 6d), with more high angle grain boundaries (Figures 6e and 6f).

The higher strength of the PC-GTAW joint is attributed to the presence of fine carbonitrides in the weld metal, higher number of high angle boundaries, and finer grain size which offers greater resistance to dislocation motion [14,15]. The fusion zone forms between the fusion line and weld metal, which denotes the actual amount of base metal melted during welding. The difference in composition of the parent metal and filler metal result in formation of UMZ, which is similar to cast parent metal and hence the lowest hardness was recorded in the region. The HAZ of both CC-GTAW and PC-GTAW retained its hardness value on par with parent metal, due to the highly stable microstructure of the super 304H at elevated temperatures [11]. The drop in yield strength of the weld joint at 600°C can be attributed to the ductility dip encountered in super 304H parent metal at that temperature range. The fracture was located in the parent metal for both the weld joints tested at all temperatures. Parent metal was used in solution annealed condition, with fine nitride precipitates to provide required grain refinement during tube manufacturing process. Such precipitates (indicated by arrow in Figure 8) may act as probable crack initiation sites during fracture at room temperature, while the fracture is found to be increasingly brittle with increase in test temperature. The decrease in elongation (ductility) with increase in temperature for both the joints was attributed to the lack of dislocations to undergo deformation. The dislocations which are available at RT to undergo plastic deformation are annihilated at high temperature due the recovery process resulted in reduction in elongation at higher temperatures [16].

Conclusions

1. PC-GTAW joint exhibited higher tensile strength and ductility (percentage of elongation) than the CC-GTAW joint at all test temperatures. Failure was located in the parent metal for all the joints tested at both room and high temperature. Hence the weld metals of both CC-GTAW and PC-GTAW joint exhibited higher strength than the parent metal.

2. Current pulsing was found to be beneficial in improving the tensile properties of GTAW joints of super 304H at all test temperatures. The improvement in strength was achieved through grain refinement, increasing the frequency of high angle grain boundaries, reduced segregation and precipitation of finer carbonitrides.
