Rare Case of Acute Aortic Dissection in a Young Non-Hypertensive and Non-Pregnant Lady

Manish Barman*, Bendaas Djamel and Joji Mathews

Department of Cardiology, Heart Care Center, Al Ahli Hospital, Doha, Qatar

Abstract

Acute aortic dissection is a catastrophic episode that usually presents as a sudden, painful, ripping sensation in the chest or back. It has an estimated annual incidence of approximately 5 to 30 per million.The primary event in aortic dissection is a tear in the aortic intima. The most important predisposing factor for acute aortic dissection is systemic hypertension. Other predisposing factors include disorders of collagen (Marfan syndrome, Ehlers-Danlos syndrome, bicuspid aortic valve, aortic coarctation, Turner syndrome, coronary artery bypass graft surgery, previous aortic valve replacement, crack cocaine use, strenuous resistance training and trauma.

Approximately half of the aortic dissection observed in women under 45 years old has been reported to be related to pregnancy. Herein, we present a case of type A aortic dissection diagnosed in a 37 year old non hypertensive, non-pregnant female. Aortic dissection is not uncommon or impossible in a young healthy and previously asymptomatic female. A high level of suspicion is required for prompt diagnosis and treatment.

Keywords: Acute aortic dissection; Non-pregnant female

Introduction

Aortic dissection is generally suspected based on a patient's history and physical examination. Patients with an aortic dissection typically present with severe, sharp or 'tearing' back pain (in dissection distal to the left subclavian artery) or anterior chest pain (in ascending aortic dissection). Painless dissection has been reported but is relatively rare [1-5]. In an analysis of 977 patients from the International Registry of Acute Aortic Dissection, only 63 patients (6.4%) had no pain [5]. Patients with painless dissection were slightly older (mean age 67 years versus 62 years) and had a type A dissection more often (75% versus 61%). A history of diabetes, aortic aneurysm or cardiovascular surgery was more common in patients with painless dissection. Presenting symptoms of syncope, heart failure or stroke were seen more often in this group. In-hospital mortality was significantly higher than for patients presenting with pain (33% versus 23%) [6,7].

All mechanisms that weaken the aortic wall, the aortic lamina media in particular, lead to higher wall stress, which can induce aortic dilatation and aneurysm formation, eventually resulting in aortic dissection or rupture.

Differential diagnosis should include

- Myocardial ischemia
- Pericarditis
- Pulmonary embolus
- Aortic regurgitation without dissection
- Aortic aneurysm without dissection
- Musculoskeletal pain
- Mediastinal tumors
- Pleuritis
- Cholecystitis
- Atherosclerotic or cholesterol embolism
- Peptic ulcer disease or perforating ulcer
- Acute pancreatitis

Routine blood tests are generally non-diagnostic and imaging studies are not performed until the patient is stabilized medically. In general terms, a bedside transthoracic echo is an invaluable tool.

Acute dissections involving the ascending aorta are considered surgical emergencies. In contrast, dissections confined to the descending aorta are treated medically unless the patient demonstrates progression or continued hemorrhage into the pleural or retroperitoneal space. Patients with suspected aortic dissection should be admitted to an intensive care unit as rapidly as possible for confirmation of the diagnosis, pain control and reduction of systolic blood pressure to between 100 mmHg and 120 mmHg. Patients who are hemodynamically unstable should be intubated. All patients should receive lifelong therapy with an oral beta-blocker to reduce systemic blood pressure and the rate of rise in systolic pressure, both of which will minimize aortic wall stress. Avoidance of strenuous physical activity is also recommended as another method to minimize aortic shear stress. A baseline thoracic magnetic resonance scan before discharge, with serial follow-up examinations at three, six and 12 months, even if the patient remains asymptomatic is recommended [8-22].

Case Presentation

A 37 years old lady, BMI 26, was admitted with complaints of acute onset, non-exertional, severe and stabbing lower chest and epigastric pain since one hour.The pain increased with movements and

deep inspiration. This was associated with nausea and one episode of vomiting. She also experienced an episode of syncope with the onset of pain. She gave no history of hypertension, diabetes or bronchial asthma. Mother of two children, last child birth 5 years ago. She has no known allergies. Non-smoker and no family history of congenital heart defects.

On presentation she was a febrile with a temperature of 36.7°C, blood pressure reading of 110/60 mmHg, a pulse rate of 50 beats/min and a respiratory rate of 18 breaths/min. She was alert and oriented. On physical examination, her pupils were round, equal, and reactive to light and accommodation. There was no jugular venous distension or hepatojugular reflux. There were no carotid bruits. The chest wall was symmetric and there was no deviation of the trachea. There was good air entry bilaterally with clear breath sounds. The point of maximal impulse was located in the left fifth intercostal space anterior axillary line. Her heart sounds had a regular rate and rhythm, with a grade II/VI mid-systolic murmur located in aortic area. There were no audible gallops or clicks. The heart sounds were not muffled and there was no pulsus paradoxus. The second heart sound was physiologically split. The abdomen was obese with no visible pulsations. The bowel sounds were normoactive. She had no palpable masses. Her abdomen was soft and nontender. Her extremities were warm to the touch, with no pallor, finger clubbing or cyanosis. Pulses were symmetrical, no radio femoral delay and there was no peripheral edema. There was no femoral bruit. No focal neurological signs. Investigations done at presentation were as follows

CBC- Mild leukocytosis, TLC 12,200/cmm, Neutrophils 74%, lymphocytes 20%, monocytes 4%, eosinophil 2%, Hemoglobin 13.2 gm/dl and platelets 2.2 lacs/cmm. Random blood sugar- 102 mg/dl, Normal liver and kidney function tests. CRP mildly elevated 11mg/dl. S amylase 55 u/L, Lipid profile- Total cholesterol 180 mg/dl, LDL 108 mg/dl, HDL 55 mg/dl. Triglycerides 132.Chest X-ray- Normal lung fields and cardiac shadow. No evidence of Mediastinal widening.

On evaluation by the cardiologist, a detailed history directed at symptoms and risk factors for aortic dissection was taken but was non-contributory. An electrocardiogram and echocardiogram were ordered as preliminary tests along with D dimer and cardiac markers. The electrocardiogram showed a normal sinus rhythm with a rate of 50 beats/min. The echocardiogram showed a dilated aortic root [5.3 cm] with intimal flap in the ascending aorta. D dimer was elevated 1.68 mg/l [normal <0.50 mg/l]. Cardiac markers were within normal range (Figures 1-3).

With regard to risk factors, she had no previous cardiac catheterization, intra-aortic balloon pump or any cardiac surgery such as valve replacement.

Diagnosis of Acute aortic dissection was made and she was immediately referred to cardiovascular surgeon foremergency surgery and underwent Bentall operation with valve replacement and aortic root replacement conduit. She required IABP and inotropic support post operatively but was successfully weaned off and recovered completely. Discharge medications included Tablet bisoprolol 1.25 mg/daily, Crestor 10 mg/daily and IE prophylaxis. She was advised regular follow up and her current status at 6 months is satisfactory with no evidence of further aortic root dilatation.

Discussion

The prevalence and incidence of thoracic aortic disease is increasing, as are the number of operations for thoracic aortic disease

Figure 3: ECHO.

[1,2,16]. In one study the overall incidence rate of 10.4 per 100,000 person-years between 1980 and 1994 was more than threefold higher than the rate from 1951 to 1980 [1]. Once ruptured, emergent repair is extremely challenging with an associated mortality in the mid 90% range [1,4]. Overall survival for TAA has improved significantly in the past 15 years [2].

The natural history of thoracic aneurysms is progressive expansion,

subsequent increased aneurysm wall stress and eventual rupture [1,3]. Aortic aneurysms can be further classified according to their morphology into fusiform or saccular categories. Aneurysms can affect different locations of the aorta: the aortic root, ascending aorta, aortic arch or the descending aorta.

There are two widely known classifications of dissections, Stanford and De Bakey. Stanford type A includes dissections that involve the ascending thoracic aorta, whereas type B dissections do not involve the ascending thoracic aorta. De Bakey type 1 dissections involve the whole aorta, type 2 dissections involve the ascending aorta and type 3 dissection involves the descending aorta. Thus, Stanford type A dissection includes De Bakey types 1 and 2, and Stanford type B equals De Bakey type 3 (Figure 4).

Many conditions can cause aneurysmal formation. The etiology may differ depending on the location of the aneurysm. The most common cause of descending aortic aneurysm is atherosclerosis, whereas the etiology for aortic root aneurysm may be associated with connective tissue disorders such as Marfan syndrome, Ehlers-Danlos syndrome and bicuspid aortic valve disease. Other etiologies include infection, inflammation, trauma, dissection and idiopathic.

Most patients are asymptomatic, and the aneurysm is discovered incidentally by chest radiography, echocardiography or CT. Aortic aneurysms may manifest with symptoms late in the course of the disease. Progressive dilation of the ascending aneurysm may cause dilation of the aortic annulus, with resultant aortic regurgitation. This represents a significant volume overload on the left ventricle, resulting in progressive left ventricular dilation and failure. Compression of the adjacent structure may lead to chronic chest pain.

Acute sudden onset of severe pain is the typical manifestation of aortic dissection, but a wide variety of symptoms can be present. The patient may have symptoms suggestive of congestive heart failure, stroke, shock or loss of distal pulse.

Presenting symptoms in acute type A aortic dissection among the patients with aortic diameters of less than 5.5 cm were back pain, radiating pain, abrupt onset of pain and neurological deficits. On presentation, 32% of patients had hypertension, 12.8% were in shock and 26% had clinical signs of pulse deficits [10]. Among the signs of aortic dissection, there was little to distinguish between patients with smaller or larger diameters of the ascending aorta, apart from more symptoms of cerebral malperfusion in the patients with smaller aortic diameters, and more congestive heart failure in the patients with larger aortic diameters (both P=0.05) [10].

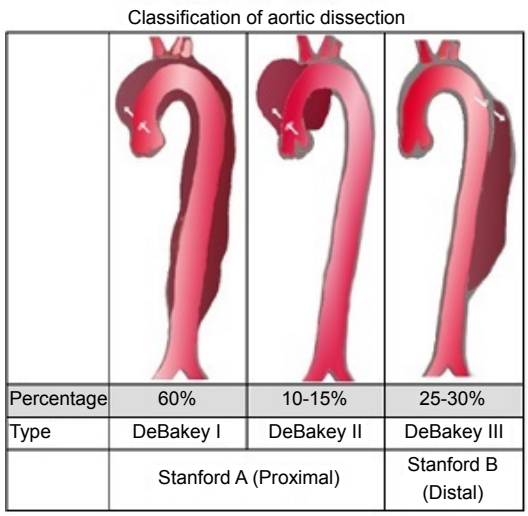

Figure 4: Classification of aortic dissection.

In aortic dissection, early diagnosis is critical because early intervention can decrease the mortality rate, which is estimated to increase by 1% to 2% per hour in the first 48 h of ascending aortic dissection [23].

A recent meta-analysis by Shiga et al. [24] that reviewed published studies of the diagnosis of aortic dissection by TEE, helical CT and MRI showed that these tests have equal and reliable diagnostic value. TEE had 99% sensitivity and 95% specificity, helical CT had 100% sensitivity and 98% specificity, and MRI had 98% sensitivity and 98% specificity [22,25].

Echocardiography provides important information not only regarding the function of the heart, but also the presence of complications of aortic dissection, such as pericardial effusion and Mediastinal hematoma [22].

It is important to differentiate between different classes of aortic dissection because treatment and prognosis vary accordingly. For example, classic type A dissection needs rapid surgical intervention, whereas classic type B dissection needs medical management. It is important to localize the tear, if possible, because the main goal of intervention is to occlude the entry point. Using two-dimensional echocardiography, the intimal flap, point of entry, and true and false lumens can easily be seen [22].

CT is the most frequent first imaging modality performed, with very high sensitivity and specificity [10,22]. MRI has the highest accuracy and sensitivity for detection of all types of dissection, with the exception of class 3, which can only be diagnosed with aortography [22]. Chest x-rays normally show a widened mediastinum. In one study 69% of patients with aortic dissection were reported to have a widened mediastinum. Significantly more patients with dissections that have diameters of less than 5.5 cm had a normal chest x-ray (12.1% versus 6.8%, P=0.05) [10].

Aortic aneurysm is usually a progressive disease that needs to be monitored closely or treated. As aneurysms grow in size, there is an increased incidence of rupture, dissection and death. Ascending aortic aneurysms grow an average of 1 mm to 4 mm every year, but in patients with bicuspid aortic valves and Marfan syndrome, the rate of growth is more rapid [22,26,27].

Aortic rupture and older age were risk factors for operative mortality, but the only variable associated with long-term mortality was increasing age. The patients who underwent surgery had an actuarial survival at one, five and 10 years of 92% (95% CI 91% to 93%), 77% (95% CI 75% to 80%) and 57% (95% CI 53% to 61%), respectively [16].

The mainstay of prevention of aortic dissection, aside from treatment of hypertension, is elective aortic surgery in patients with dilated ascending aortas. Guidelines for timing of aortic root repair are based on clinical observations by experienced clinicians and surgeons, and a consensus based on clinical series and patient characteristics. There is a consensus that surgery to prevent rupture or dissection of the ascending TAA should be recommended when the ascending aortic diameter reaches 5.5 cm for non-Marfan patients and 4.5 cm in Marfan patients [10-14,16].

Conclusion

Acute aortic dissection is a life-threatening disease with a very high rate of cardiovascular morbidity and mortality. The most important and common risk factor is the systemic hypertension which has been reported in the 70% of the patients with aortic dissection. Most of the aortic dissection observed in young women has been reported to be related to pregnancy. Pregnancy is considered to be an independent risk factor for aortic dissection however underlying mechanisms are not completely known. Since mortality increases dramatically every hour when the diagnosis and treatment of aortic dissection are not performed, it is very important to make differential diagnosis quickly in such cases. Selection of treatment modality in aortic dissection is based on the type of dissection. In Type A dissection aortic repair is recommended. Type B dissection is usually asymptomatic rather than Type A dissections and probably many patients are overlooked. In Type B dissection, medical treatment is the first choice and involves nitrates and β-blockers combination.
