Abstract

The metabolic syndrome represents a cluster of closely connected premorbid risk factors or diseases with visceral obesity, prediabetes or type 2 diabetes, hypertension and low dyslipidemia as established traits affecting about 20 % of adults in developed countries. This syndrome develops on a common soil with overnutrition, low physical activity and psychosocial stress as major components. Common comorbidities are fatty liver, sleep apnoea, and gout with cardiovascular complications, nephropathy and type 2 diabetes as ‘endstage’ diseases. The term metabolic vascular syndrome was proposed to signal premorbid cardiovascular state and increased cardiovascular morbidity. Thus, a rational diagnostic is needed to elucidate the complex cluster of diseases as basis for an integrated therapy. There is a clear priority for life style intervention however most diseases of the metabolic syndrome need medical treatment. Medical treatment of single traits has to take into account possible pleiotropic or adverse effects on the other traits. Here we present the pros and cons of major medical interventions in type 2 diabetes, hypertension, dyslipidemia and hypercoagulation in the context with the metabolic syndrome.

Keywords: Actigraphy; Sleep disorders; Attention deficit and hyperactivity disorder; Pediatric population

Introduction and Definition

Pre-diabetes or type 2 diabetes, hypertension and dyslipidemia are core components (Table1). Moreover, clinical manifestations include increased risk of non-alcoholic fatty liver (NAFLD), gout, sleep apnoea, depression cancer and sexual dysfunction. It is mainly caused by overeating together with low level of physical and socio-cultural activity in societies with a rapid transition to western life style and aging populations. The relationship between type 2 diabetes, hypertension and gout was first described by Maranon and Kylin [2] in 1956 linked visceral (masculine) obesity to glucose intolerance and dyslipidemia what was later described as ‘plurimetabolic syndrome’ by G. Crepaldi [3,4]. In 1981 we gave a first definition of the metabolic syndrome: "By this term, we understand the simultaneous occurrence of obesity, hyper- and dyslipoproteinemia, maturity onset diabetes (type 2), gout, and hypertension, associated with an elevated incidence of atherosclerotic vascular diseases, fatty liver, and gallstones in overfed, physically inactive and genetically predisposed people” [5]. The rise of the metabolic syndrome into one of the most cited syndromes however started when G. Reaven presented insulin resistance as the common soil for type 2 diabetes, hypertension and dyslipidemia in his 1988 Banting Lecture and called it syndrome X, more or less as synonym for insulin resistance syndrome [6,7]. With a rapid change in life-style around the globe a pandemic of the diseases of the metabolic syndrome was observed affecting 20 to 50 % of the adult population [8]. A first world-wide definition was published by the International Diabetes Federation (IDF) in 2006 [9] (Table 1) with the American Heart Association (AHA) /National Cholesterol Education Program III (NCEP III) criteria as one of the most frequently used competitor which better meets cardiovascular risk [10]. To overcome confusion by too many competing definitions a unifying definition was developed in 2009 (Table 1) [11].

Table 1: Definition of the metabolic syndrome based on metabolic syndrome criteria by AHA/ NCEP III [9] and IDF [9] as well as the American Heart Association (AHA) /National Cholesterol Education Program III (NCEP III) criteria as one of the most frequently used competitor which better meets cardiovascular risk [10]. To overcome confusion by too many competing definitions a unifying definition was developed in 2009 (Table 1) [11].
Here we consider the metabolic syndrome as a cluster of premorbid risk factors and/or developed diseases with a common soil in malnutrition, lifestyle factors, socio-economic conditions and genetic predisposition. These conditions not only affect diseases of the metabolic syndrome but also interact with classical risk factors such as smoking and low-density lipoprotein (LDL)-cholesterol. Recently increased inflammatory activity and endothelial dysfunction could be identified as components of the metabolic syndrome [12]. Therefore the term metabolic vascular syndrome was proposed to signal premorbid cardiovascular state and increased cardiovascular morbidity [13]. Type 2 diabetes and cardiovascular diseases thus may be considered as ‘end stage’ sickness of the metabolic syndrome [14]. With this in mind the metabolic syndrome provides an integrated approach for rational diagnostic and prevention of a broad spectrum of intricately connected diseases.

Pathophysiology

The metabolic syndrome rose to increased clinical consideration and scrutiny together with the worldwide epidemic of obesity and diabetes. However the pathophysiological mechanisms leading to this cluster of metabolic diseases and eventually cardiovascular complications are not completely understood [15]. Although insulin resistance is a core abnormality of individuals with metabolic syndrome [16], there is no sufficient evidence for a causal link between the two [17]. The most promising hypothesis for a single causal link between the development of the different traits of the metabolic syndrome and atherosclerosis is chronic low grade inflammation, particularly in dysfunctional adipose tissue [18]. The onset of abdominal obesity is central to the alteration of normal adipose tissue function with decreased glucose uptake, increased storage of fat as well as increased release of non esterified fatty acids (FFA) into the circulation. In obesity adipose tissue is infiltrated by macrophages which influence its cytokine production. There is an increased release of interleukin 6, tumor necrosis factor α (TNFa), monocyte chemo attractant protein 1 (MCP1) or C-reactive protein (CRP) whereas release of adiponectine is decreased. Whether the inflammatory response of the visceral adipose tissue is primarily induced by intracellular fat accumulation or by infiltration of activated macrophages is still a matter of debate [19]. Thus, the impact of changes in visceral adipose tissue can be summarized as a state of systemic lipotoxicity and low grade inflammation. Inflammatory cytokines are involved in the induction of endothelial dysfunction and insulin resistance [20]. Furthermore the insulin resistant state of obesity is characterised by increased plasma levels of free fatty acids that have cardiotoxic effects and impair the production of endothelial vasodilators [2,22].

In addition to these systemic effects of visceral obesity there is a local impairment of cardiac and vascular function by dysfunctional perivascular adipose tissue (PVAT) [23]. Under normal conditions PVAT produces different cytokines and hormones which contribute to vascular relaxation. In the obese state PVAT mass, like visceral adipose mass is increased and its anticontractile effects are diminished. Therefore PVAT in obesity may contribute to endothelial function and hence atherosclerosis and plays a key role in the development of vascular insulin resistance [24,25].

A common hypothesis describes metabolic susceptibility as central factor for the development of the metabolic syndrome. This metabolic susceptibility is determined by polygenic variability of individuals [26] but also gene-environment interactions [20,27]. Once a sedentary lifestyle with decreased physical activity and high caloric intake leads to the acquisition of body fat and development of overweight and obesity, a susceptible individual is at high risk to develop the metabolic syndrome and cardiovascular consequences. Genome wide association studies have identified a lot of potential genetic variants that may contribute to development of metabolic syndrome, however, the complexity of its different single traits with their own genetic determinants is a major challenge for the genetic studies [28]. Despite this complex pathophysiology as soil for the metabolic syndrome and associated diseases, we also have to keep in mind the strong impact of lifestyle and environment which lead to epigenetic regulation such as the methylation of desoxyribonucleic acids (DNA) nucleotides and the modification of histone proteins surrounding the DNA double helix. These mechanisms as key regulators of gene expression can explain inter-individual variation of phenotypes [29]. Recent studies demonstrated a close relationship between intrauterine growth retardation and metabolic disease in adulthood. Low birth weight has also been associated with hypertension and susceptibility to cardiovascular diseases [30]. In addition to heritable regulation of the epigenome, there is also evidence of lifestyle-related modification of genes in adulthood [31].

A completely new area of metabolic and genetic research is the so called intestinal microbiome. Intestinal bacteria can influence immunological and inflammatory processes as well as gene expression within the intestinal wall. Animal studies demonstrated that gut microbiota can transfer metabolic diseases between individuals [32].

As a conclusion, there are several genetic and environmental factors which contribute to the development of both metabolic disorders which are summarized as metabolic syndrome and cardiovascular disease. It is conceivable that metabolic and cardiovascular disorders develop in parallel and and eventually interact in a vicious cycle. Therefore, the term metabolic vascular syndrome might be the most comprehensive description of this cluster of diseases [13].

Comorbidities and related cardiovascular risk factors

In the majority of cases which meet the criteria of the unifying definition or NCEPIII criteria we find comorbidities and cardiovascular risk factors which are summarized in Table 2. Among these broad spectrum NAFLD and albuminuria have been identified as major risk factors for both type 2 diabetes and cardiovascular disease.
Therefore abdominal palpitation and ultrasound measurement of the liver and measurement of liver enzymes is good clinical practice in cases with metabolic vascular syndrome. The same applies for measurement of albumin to creatinine ratio in urine. However there don’t exist any specific complication or comorbidity. The majority of related risk factors can be linked to visceral obesity or ectopic fat but also can be found in single diseases such as hypertension or dyslipidemia. For example hypertriglyceridermia is associated with an increase in highly atherogenic small dense LDL. Risk scores (e.g. Prospective cardiovascular Muenster [PROCAM]-Score) are useful to support physician’s decision making [13].

### Consequences for an integrated prevention of ‘end-stage diseases’

#### Lifestyle intervention

From a clinical viewpoint type 2 diabetes and cardiovascular disease such as coronary heart disease, cerebrovascular disease and peripheral arterial disease can be considered as end-stage diseases developing on the complex prodiaetic and proatherogenic soil of the metabolic vascular syndrome. The rational of this concept is essential for lifestyle intervention and improving socio-economic conditions, avoiding stress exposure and as guide for regulation of food production and trade. This is a challenge for the whole society.

So far best evidence for modifiable risk factors for prevention of the metabolic vascular syndrome is available for changes in nutrition and increased physical activity to reduce overweight and insulin resistance. There exists now a bulk of evidence that with effective lifestyle intervention the incidence of type 2 diabetes can be reduced by about 50 % [35,36]. Lifestyle intervention trials with similar integrated approach including psychosomatic treatment tools – have also successfully been performed for the prevention, primary and secondary, of cardiovascular diseases [37-39].

#### Medical intervention balance – antihypertensive drugs

Subjects with the metabolic vascular syndrome are at high risk for development of cardiovascular events according to the Systematic Coronary Risk Evaluation (SCORE) model even if they have grade 1 hypertension [40]. International guidelines recommend systolic blood pressure control to a level <140 mmHg and diastolic blood pressure control to < 90 mmHg depending on age, individual risk and comorbidities with focus on kidney disease [13,41]. To reach this treatment goal 4 classes of antihypertensive drugs are recommended as first line treatment by the European Society of Hypertension/European Society of Cardiology (ESH/ESC) guidelines: angiotensin converting enzyme (ACE) inhibitors/angiotensin II receptor (ARB) blockers, calcium channel blockers, beta blockers and diuretics. While blood pressure lowering effect and cardiovascular benefit is similar for these 4 classes of antihypertensive agents there are some differences in metabolic effects which should be considered in patients with the metabolic vascular syndrome. Beta blocker can increase body weight and – in combination with diuretics – the incidence of type 2 diabetes [13,42,43] however, newer beta blocker e.g. nebivolol and carvedilol did not affect insulin sensitivity and should therefore be preferred in patients with the metabolic vascular syndrome [44,45]. The ACCOMPLISH (Avoiding cardiovascular events in combination therapy in patients living with systolic hypertension) trial demonstrated a higher rate of cardiovascular events in patients receiving a combination therapy of a thiazide diuretic and an ACE inhibitor compared to patients with an ACE inhibitor/calcium channel blocker [46]. So far other randomized trials confirmed this superiority of calcium channel blocker over a diuretic treatment [41]. The use of thiazide diuretics can induce hypokalemia which may worsen glucose tolerance and provoke cardiac arrhythmias [47]. Due to their unfavourable metabolic effects beta blocker and diuretics should only be considered as additional blood pressure lowering drugs in metabolic syndrome in particular if free of vascular disease. If thiazide diuretics are used the addition of a potassium sparing diuretic agents could reduce the risk of hypokalemia [48].

ACE-inhibitor or ARB and calcium channel blocker should be preferred for the treatment of hypertension in patients with the metabolic vascular syndrome because they have no negative effect on insulin sensitivity or body weight. ACE-inhibitors/ARB are most effective in reducing proteinuria and preventing the progression of diabetic nephropathy whereas calcium channel blocker are the best choice for the prevention of stroke [49,50]. There is no evidence of an additional benefit of the newer ARB compared to ACE-inhibitors in patients with the metabolic vascular syndrome.

In the ONTARGET (Ongoing telmisartan alone and in combination with ramipril global endpoint) trial ARB telmisartan was associated with a significantly higher incidence of diabetes while no effect on primary objectives – major cardiovascular events was achieved [51]. In the HOPE (Heart outcomes prevention evaluation) study however with ACE inhibitor ramipril fewer patients were diagnosed with diabetes at the end of the study as in the placebo group 52. This could not be confirmed in the DREAM (Diabetes reduction assessment with ramipril and rosiglitazone medication) trial in people with impaired glucose tolerance where ramipril had no effect on the incidence of diabetes as a primary objective [53]. The same applies for ARB valsartan in the NAVIGATOR (Nateglinid and valsartan in impaired glucose tolerance outcomes research) trial – a prospective primary prevention study with cardiovascular complications as primary objective and diabetes as secondary objective [54].

To achieve blood pressure goals most patients need a combination therapy of 2 or more antihypertensive drugs. As recently recommended by the ESH/ESC Guidelines the initiation of a combination therapy instead of a monotherapy should be considered in patients with >160 mmHg systolic and/or >100 mmHg diastolic blood pressure. With combinations a prompter response in a larger number of patients to reach target blood pressure and a higher adherence of patients to the therapy was achieved [41]. Preferred drug combinations for initial treatment are that between ACE-inhibitor or ARB and calcium channel blocker whereas a combination of beta
blocker and thiazide diuretic is not recommended as initial treatment for patients with the metabolic vascular syndrome [42].

In conclusion national and international guidelines recommend in patients with the metabolic vascular syndrome an individualized approach with age, comorbidities and presence or absence of end stage diseases as guide to decision.

**Antidiabetic drugs**

Evidence with antidiabetic drugs for the prevention of type 2 diabetes in people with abnormal glucose tolerance is available only for metformin [55], acarbose [56] and thiazolidinediones [57-59].

Metformin has consistent evidence to prevent progression of impaired glucose tolerance (IGT)/impaired fasting glucose (IFG) to type 2 diabetes. In the DPP Diabetes prevention program sStudy the reduction in incidence of diabetes was 31% vs. 58% with lifestyle intervention alone [55]. The reduction of newly diagnosed diabetes in the STOP NIDDM (Study to prevent non-insulin-dependent diabetes mellitus) trial with a glucosidase inhibitor acarbose was in the same range if the same diagnostic criteria were used as in the DPP [56]. Despite glitazones were very effective to reduce incidence of newly diagnosed diabetes and had pleiotropic effects on blood pressure, biomarkers of inflammation and endothelial dysfunction [60-62] they cannot be recommended because of serious adverse effects such as edema, congestive heart failure and bone fractures for primary prevention of diseases of the metabolic vascular syndrome [63].

Acarbose, a weight reducing intestinal lipase inhibitor reduced incidence of diabetes in obese subjects with abnormal glucose tolerance by – 31 % [64]. Metformin in addition had beneficial effects on weight and minor effects on blood lipids, but did not affect blood pressure in the DPP 64 and BIGPRO (Treatment with metformin of non-diabetic men with hypertension, hypertriglyceridaemia and central fat distribution) trial [66]. However, none of the primary prevention trials with metformin has shown an effect on major cardiovascular events, even in the long term follow-up after termination of the studies [65].

Orlistat, a weight reducing intestinal lipase inhibitor reduced incidence of diabetes in obese subjects with abnormal glucose tolerance by ~ 31 % [64]. Metformin in addition had beneficial effects on weight and minor effects on blood lipids, but did not affect blood pressure in the DPP 64 and BIGPRO (Treatment with metformin of non-diabetic men with hypertension, hypertriglyceridaemia and central fat distribution) trial [66]. However, none of the primary prevention trials with metformin has shown an effect on major cardiovascular events, even in the long term follow-up after termination of the studies [65].

Lipid lowering drugs

Dyslipidemia with hypertriglyceridermia and low high density lipoprotein (HDL) is in the majority of cases associated with an increase in small dense LDL, a lipoprotein subfraction with high atherogenic potential which is intricately connected with insulin resistance and low grade inflammation (Figure 2) [73]. This lipid triad together with high cardiovascular risk provides a rational pathophysiological basis for the use of statins as first line drug. Statins have a grade I evidence for primary [74,75] and secondary [76,77] prevention of cardiovascular disease. In the case of dyslipidemia with hypertriglyceridermia they can be used in combination with fibrates. In the ACCORD (Action to Control Cardiovascular Risk in Diabetes) trial [78] and FIELD (Fenofibrate Intervention and Event Lowering in Diabetes) [79] in patients with hypertriglyceridermia fenofibrate had an additional beneficial effect on cardiovascular outcome when used in combination with statins. As shown in a metaanalysis of data from 170000 participants with intensive statin treatment reduction of cardiovascular events was mainly due to LDL-cholesterol lowering efficacy [80]. However in the JUPITER...
(Justification for the use of statin in prevention: an intervention trial evaluating rosuvastatin) study in patients with elevated high sensitive C-reactive protein (hsCRP) but LDL-cholesterol in the normal range rosuvastatin, one of the strong statins, reduced major cardiovascular events versus placebo [81]. Beneficial effects on the lipid triad in patients with the metabolic vascular syndrome have been demonstrated for atorvastatin and rosuvastatin [8,83]. In long term studies, however, statins increased the risk of newly diagnosed diabetes [83]. This is far outweighed by the cardiovascular benefit. In a metaanalysis intensive dose statin therapy had a number needed to harm for one case of new elevated hsCRP. This clustering of risk factors can be used as a guide for interventions to increase HDL-cholesterol [92].

The metabolic vascular syndrome in all patients with hypertension. In established trait of the metabolic syndrome in all definitions (Table 1). Analysis revealed a greater benefit of anticoagulatory prevention for patients with the metabolic vascular syndrome and type 2 diabetes [98]. According to this critical concept to increase HDL-cholesterol to protect the vessel weight of atherothrombogenic risk factors randomised trials and meta analysis have demonstrated a significant reduction of cardiovascular events in patients with dyslipidemia and metabolic vascular syndrome treated with gemfibrozil versus placebo [86-88]. Gemfibrozil, however, is contraindicated for combination with statins because of high rates of myopathies and increased risk of rhabdomyolysis [89]. Low HDL is an established trait of the metabolic syndrome in all definitions (Table 1). However the concept to increase HDL-cholesterol to protect the vessel wall was not supported by recently published trials with nicotinic acid [90] and cholesteryl ester transfer protein (CETP) inhibitors [91,92] showing increased rates of serious adverse events but no benefit for primary objectives. Therefore, ESC Guidelines no longer support drug interventions to increase HDL-cholesterol [92].

The ESH recommends are careful diagnostic of all parameters of the metabolic vascular syndrome in all patients with hypertension. In these individuals premorbid risk factors of the metabolic vascular syndrome are common inclusive the lipid triad, albuminurea and elevated hsCRP. This clustering of risk factors can be used as a guide to prescription of statins [41].

### Anticoagulatory treatment

Patients with a metabolic vascular syndrome have a complex pathophysiology of cellular and humoral coagulation with activated platelet aggregation, impaired fibrinolysis and elevated factors of the coagulation cascade as major components. This is particularly critical in patients with type 2 diabetes [94,95]. Subjects with diabetes have a higher rate of major cardiovascular events but inferior outcomes and effects of intervention after acute coronary syndrome [96]. This can be at least partially explained by harmful alterations in the coagulation associated with the metabolic syndrome. According to this critical weight of atherothrombogenic risk factors randomised trials and meta analysis revealed a greater benefit of anticoagulatory prevention for patients with diabetes and metabolic vascular syndrome.

Acetyl salicylic acid (aspirin) is widely used for secondary prevention in type 2 diabetes. Recently published metaanalysis however reveal no significant impact on mortality while bleeding episodes are significantly increased [97,98]. No positive outcome data on primary prevention are available for aspirin and the new platelet aggregation inhibitors such as clopidogrel, prasugrel and ticagrelor. The benefit of low dose aspirin (75-100 mg/d) for secondary prevention is well documented for patients with type 2 diabetes [97]. In the CAPRIE (Clopidogrel versus aspirin in patients at risk of ischaemic events) study clopidogrel 74 mg was significantly more effective in patients with type 2 diabetes compared to aspirin [99]. Incidence of major cardiovascular events (MACE) with clopidogrel was 5.32 %, with aspirin 5.83 % (RR 8.7 %, p=0.043). Benefit of clopidogrel was even higher in patients with peripheral arterial disease. Therefore, the American Diabetes Association (ADA) recommends clopidogrel in very high risk groups with type 2 diabetes. This could be applied in general for type 2 diabetes with metabolic vascular syndrome. New platelet aggregation inhibitors prasugrel and ticagrelor have shown a significantly higher benefit in acute coronary syndrome versus clopidogrel [100], however, large outcome trials in patients with stable atherosclerotic disease are not yet published. Diabetes is an independent risk factor for atrial fibrillation and thrombolic complications. Therefore, risk scores for stroke and systemic embolism result in an indication for anticoagulant therapy with vitamin K antagonists (cumarins) or direct-acting oral anticoagulants (apixaban, dabigatran, rivaroxaban). No data from controlled prospective trials are available in diabetes comparing old and new anticoagulants.

### Conclusion

In conclusion, a rational diagnostic is needed to elucidate the complex cluster of diseases as basis for an integrated therapy by using synergistic and pleiotropic effects to avoid polypharmacy which is written down in the new German Guideline Metabolic Vasculare Syndrome [13].

### Future directions

In the process of globalization with a rapid transition from traditional life habits to westernized life style in developing countries and aging societies in developed countries we will see a further increase in patients with the metabolic vascular syndrome. There is a common soil of malnutrition and inertia which gives a priority to life style intervention for the whole society. The components of the metabolic vascular syndrome and associated risk factors can be used as a simple guide for an individualized medical treatment approach to use synergistic effects of drugs and avoid counterproductive adverse effects.
